

**Ozone National Ambient Air Quality Standard Health Exceedances on July 15, 2021**

**Exceedance Locations and Levels**

On Thursday, July 15, 2021, there were no exceedances in New Jersey of the National Ambient Air Quality Standard (NAAQS) for ozone (daily maximum 8-hour average of 70 ppb). See Table 1.

**Table 1. New Jersey Ozone Concentrations on 7/15/2021**

| STATION               | Daily Maximum 8-Hr<br>Average (ppb) |
|-----------------------|-------------------------------------|
| Ancora State Hospital | 40                                  |

## **Weather**

Bermuda high pressure set up over much of the eastern United States on Thursday, July 15<sup>th</sup>. This brought hot and humid conditions to the region. Meanwhile, a surface trough stationed over the I-95 corridor allowed for the mixing of pollutants aloft to the surface, concentrating much of the ozone formation in this area. Although meteorological conditions were conducive for ozone formation, scattered cumulus clouds over the area were able to limit this formation enough in most areas, which led to there being only a few isolated exceedances in Pennsylvania and New York.

High pressure centered over Bermuda moved offshore during the morning hours of July 15<sup>th</sup>. This allowed for another hot and humid day across the region, with temperatures reaching the upper 80s across much of the region. As the afternoon progressed, a sea breeze developed over Long Island and New Jersey as a surface trough moved over the I-95 corridor. Some brief, isolated storms developed along these boundaries, with plenty of fair-weather cumulus developing throughout much of the region. Calm to light southwest winds were observed in New Jersey and eastern Pennsylvania, while a light southerly flow over Connecticut was observed and a light southeast wind over the New York City Metropolitan area. This allowed for localized transport of emissions from cars, trucks, and industry along the I-95 corridor. The surface trough provided vertical motion in the atmosphere, mixing down pollutants aloft, enhancing ozone formation to areas along the I-95 corridor, where isolated locations in Pennsylvania and New York reached the unhealthy for sensitive groups category. Despite these favorable conditions, spotty cloud cover across the area was able to limit ozone formation in other locations, where moderate air quality was observed throughout much of the nonattainment area.

Favorable weather conditions, along with localized transport of pollutants were all factors that led to the isolated exceedances in Pennsylvania and New York.

## **Where Did the Air Pollution that Caused Ozone Come From?**

Figures 2, 3, and 4 show the back trajectories starting at different wind heights for the monitored exceedances on July 15, 2021. The figures illustrate where the air came from during the 48 hours preceding the 8-hour ozone standard exceedances. Three monitoring stations were chosen to model back trajectories and are listed in Table 4.

**Table 4. Monitoring Stations with an 8-hr Ozone Exceedance that were Selected to Run 48-hr Back Trajectories**

| STATE | STATION      | Daily Maximum 8-Hr Average (ppb) |
|-------|--------------|----------------------------------|
| NY    | White Plains | 71                               |
| PA    | Bristol      | 77                               |
| PA    | NEA          | 71                               |

Back trajectories from July 15<sup>th</sup> show that air at the surface traveled off of, and along, the Mid-Atlantic coast, while air at upper levels came from a westerly direction and traveled along a large area of high pressure over the region. Surface trajectories were able to pick up emissions at the ground while the gentle sinking motion aloft, due to the influence of a surface trough, allowed pollutants to mix down to

the surface. This, in combination with the favorable meteorological conditions mentioned above, led to the exceedances in Pennsylvania and New York.

The surface-level back trajectories (Figure 2) show that air originated over Virginia and travelled in a northeasterly direction. From there, trajectories traversed over the Chesapeake Bay Region and Delaware, where they likely picked up emissions from cars, trucks, and industry. Traveling at ground level during their path, the trajectories continued to pick up emissions as they moved northeastward over Philadelphia, where two trajectories would arrive at their destinations. One additional air parcel originated off the coast of New Jersey and travelled in a westerly direction. The parcel then took a sharp turn and moved in a northeasterly direction. Under the influence of high pressure, the air parcel continued in clockwise direction around its destination in New York, allowing optimal time to pick up ozone precursors from previously polluted air.

Mid and upper-level back trajectories (Figures 3 & 4) followed similar transport pathways. Air Parcels originated over parts of Tennessee, Kentucky, and Illinois, before travelling in a generally eastern direction, while passing over many states during transit. Trajectories then traversed in a clockwise rotation following the perimeter of high pressure, over the heavily populated and industrialized region of the Ohio River Valley. Air parcels proceeded to travel over central and southern portions of Pennsylvania, along with portions of northern Maryland. It is likely, after exiting this region that trajectories accumulated pollutants from various metropolitan centers such as Pittsburgh and Washington D.C. before arriving at the exceedance locations in Pennsylvania and New York. Under the influence of persistent high pressure, as well as the presence of a surface trough, air at both levels made a descent to lower elevations which may have provided an opportunity for polluted air aloft to mix down to the surface.

Figure 5 shows the National Air Quality Index observed on July 14th, the day prior to this exceedance event. As shown in the figure, a few isolated areas in the nonattainment zone reached the moderate category the day before, indicating that previously polluted air was transported to the surface from upper levels. Despite the lack of widespread moderate and unhealthy for sensitive groups air quality in the region, southwesterly winds were able to transport a plume of ozone precursors into Pennsylvania and New York from upwind locations including the Baltimore area. All these conditions, along with favorable meteorological conditions mentioned above, allowed ground level ozone concentrations to reach the USG category in isolated locations.

### **How is Ozone Created?**

Ground-level ozone is an air pollutant known to cause several health effects and negatively impact air quality and the environment in New Jersey. Ozone is formed when oxides of nitrogen (NO<sub>x</sub>) and volatile organic compounds (VOCs) react in the presence of sunlight. Ozone can irritate any person's lungs, but the effect may be more pronounced for those with existing lung-related deficiencies, and therefore, one should take extra precautions on bad ozone days.

### **Find Out About Air Quality Every Day**
